

# Smashing The Stack

A detailed look at buffer overflows as  
described in  
***Smashing the Stack for Fun and Profit***  
by Aleph One

# Process Memory Organization

- Text
  - Fixed by program
  - Includes code and read-only data
    - Since read-only, attempts to write to this typically cause seg fault.
- Data
  - Static variables (both initialized and uninitialized)
- Stack
  - Usual LIFO data structure
  - Used because well suited for procedure calls
  - Used for dynamic allocation of local variables, passing of parameters, returning values from functions

# Process Memory Regions

# Stack Region

- Stack is a contiguous block of memory containing data
  - Size dynamically adjusted by OS kernel at runtime
- Stack pointer (SP) register: points to top of stack
  - Bottom of stack at fixed address
- Stack Frame
  - Parameters to a function
  - Local variables of function
  - Data necessary to recover previous stack frame
    - Including value of instruction pointer (IP) at time of function call
  - PUSHed onto stack on function call, POPped on return

# Stack Region

- Assumptions
  - Stack grows down (toward lower addresses)
  - SP points to last address on stack (as opposed to pointing to next free available address)
- Frame Pointer (FP) a.k.a. local base pointer (LP)
  - Points to fixed location within frame
  - Local variables and parameters referenced via FP because their distance from FP do not change with PUSHes and POPs
    - Actual parameters PUSHed before new frame creation, so have positive offsets, local variables after, so negative offsets
  - On Intel CPUs, the EBP (32-bit BP) register is used

# On Procedure Call...

- Procedure prolog (start of call)
  - Save previous FP (to be restored at proc. exit)
  - Copy SP into FP to create new FP
  - Advance SP to reserve space for local variables
- Procedure epilogue (end of procedure)
  - Stack is cleaned up and restored to previous state
- Often special instructions to handle these
  - Intel: ENTER and LEAVE
  - Motorola: LINK and UNLINK

# Example

example1.c:

```
-----  
void function(int a, int b, int c) {  
    char buffer1[5];  
    char buffer2[10];  
}
```

```
void main() {  
    function(1, 2, 3);  
}
```

-----

ebp 482

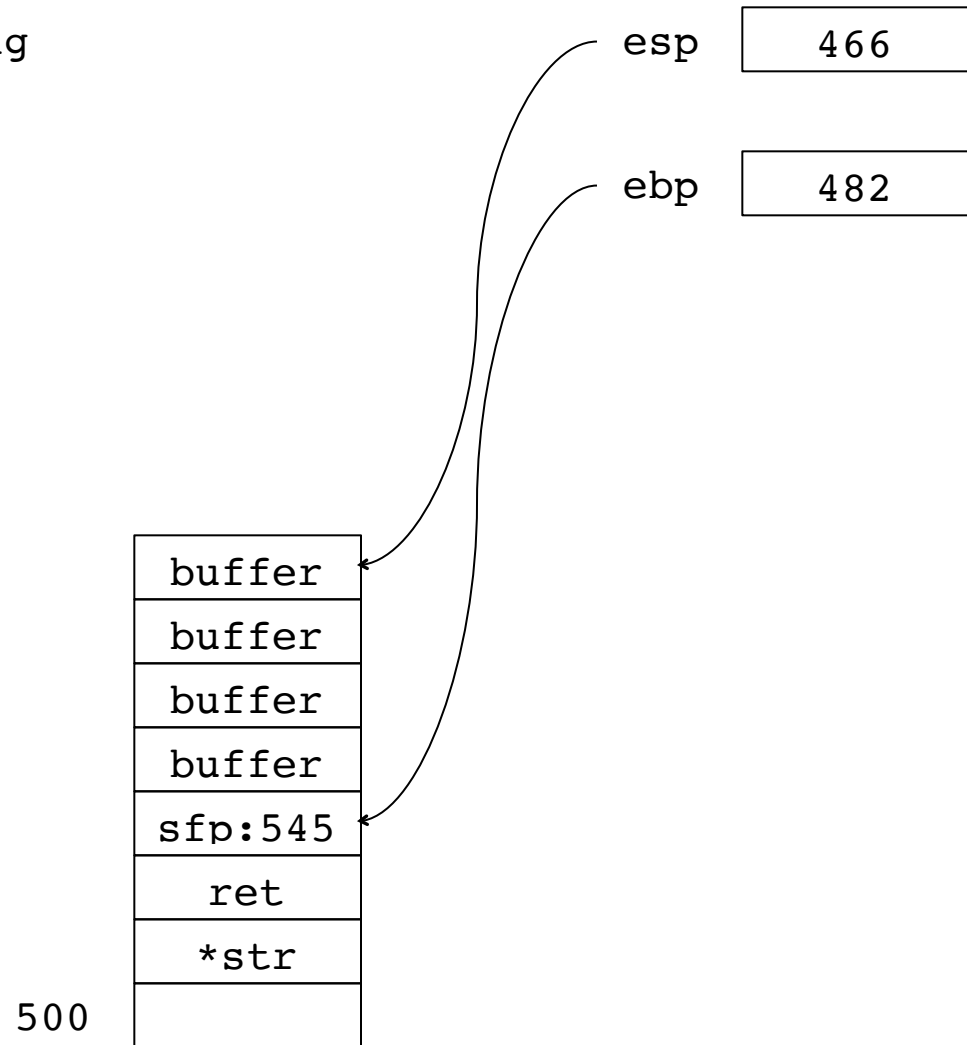

# Another Example

example2.c

```
-----  
void function(char *str) {  
    char buffer[16];  
  
    strcpy(buffer, str);  
}  
  
void main() {  
    char large_string[256];  
    int i;  
  
    for( i = 0; i < 255; i++)  
        large_string[i] = 'A';  
  
    function(large_string);  
}  
-----
```

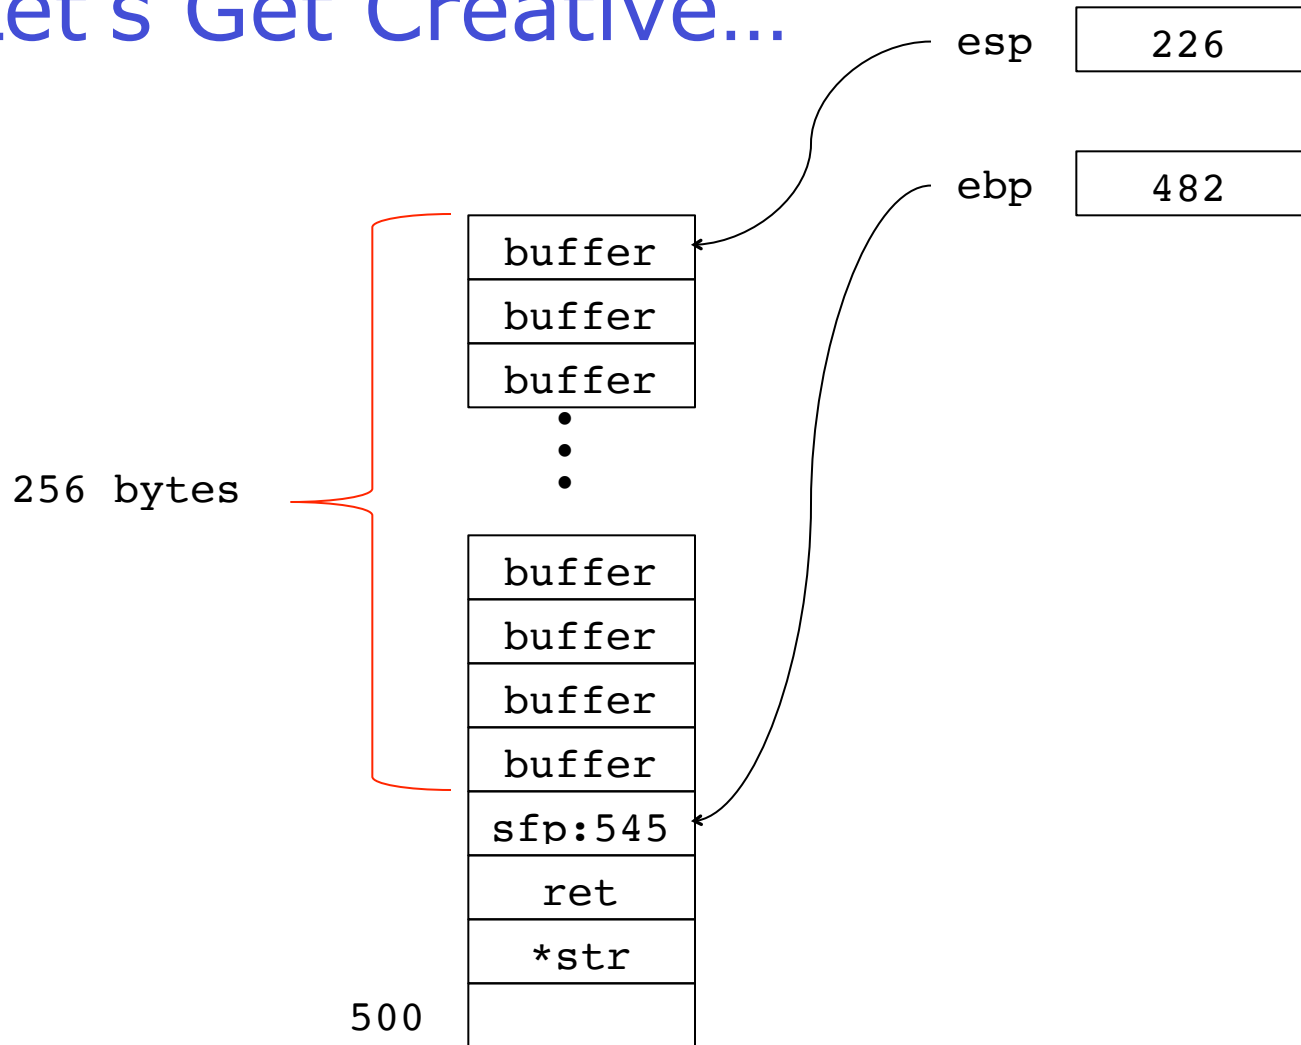

Note that code copies a string without using a bounds check (programmer used `strcpy()` instead of `strncpy()`). Thus the call to `function()` causes the buffer to be overwritten, in this case with `0x41414141`, the ASCII code for 'A'

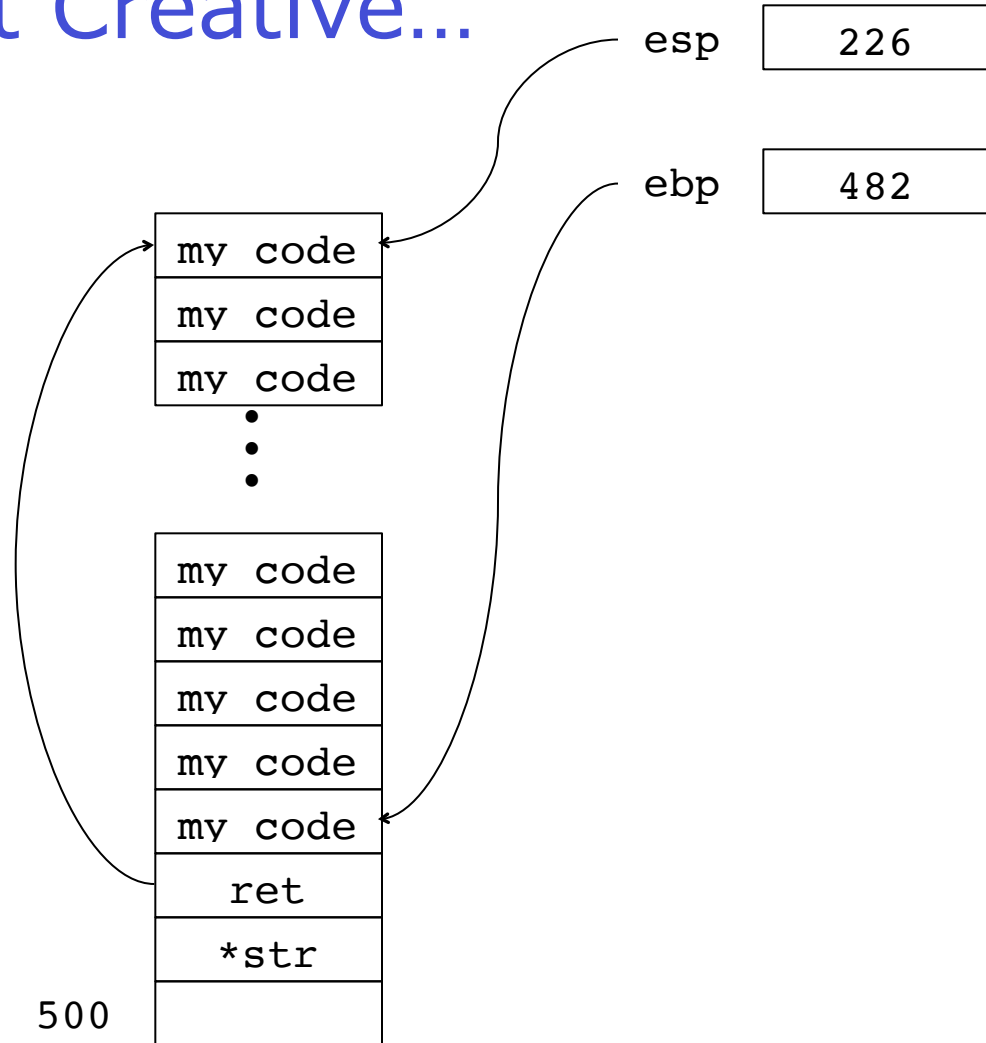

# Let's Get Creative...

Let's assume now that buffer is a bit bigger than 20 bytes. Say, e.g., 256 bytes.

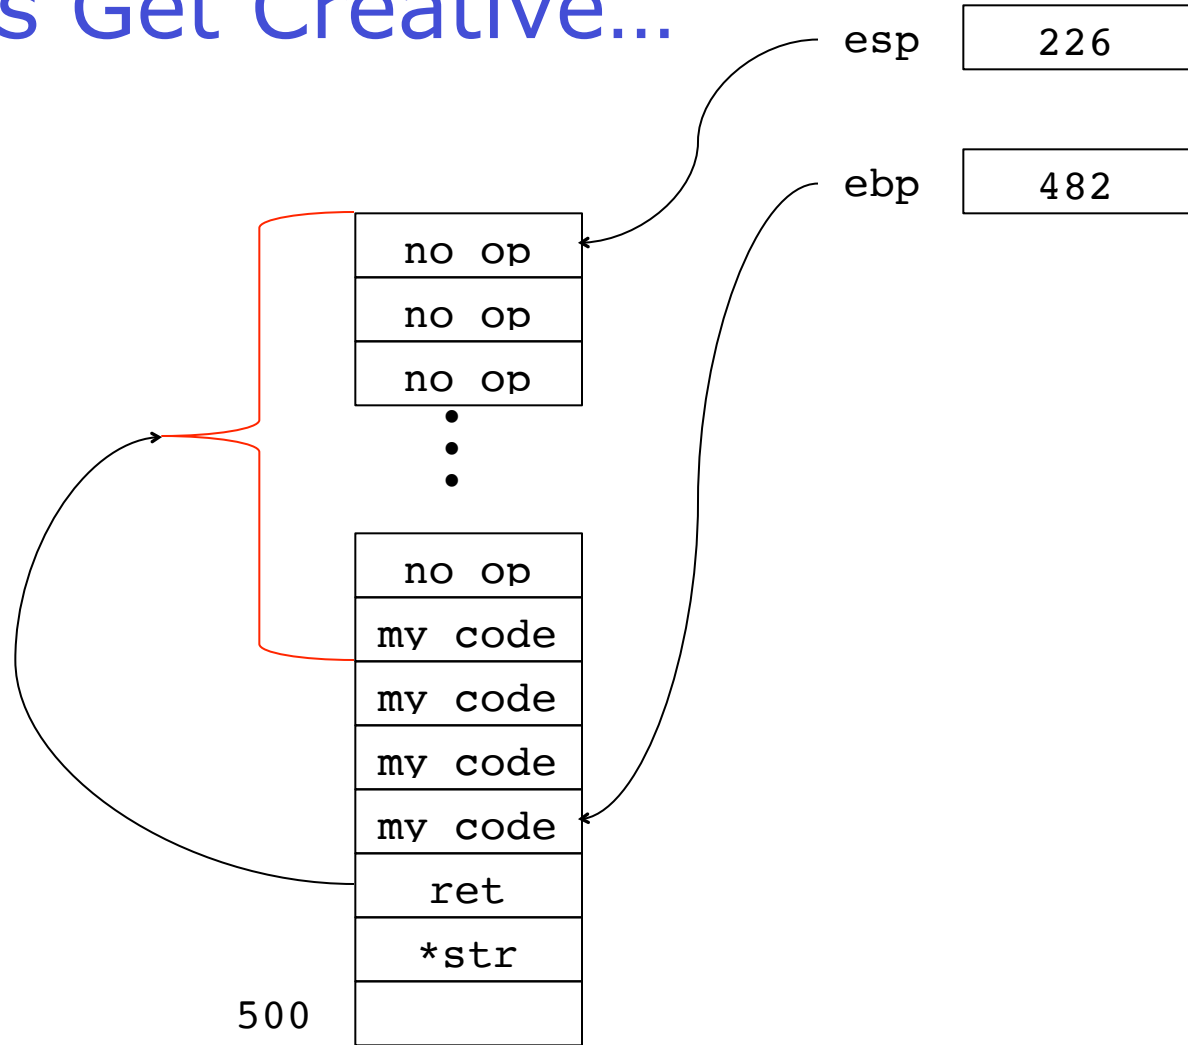

# Let's Get Creative...

Let's assume now that buffer is a bit bigger than 20 bytes. Say, e.g., 256 bytes. If we know assembly code, we can feed code in as a string, and overwrite the return address to point to this.

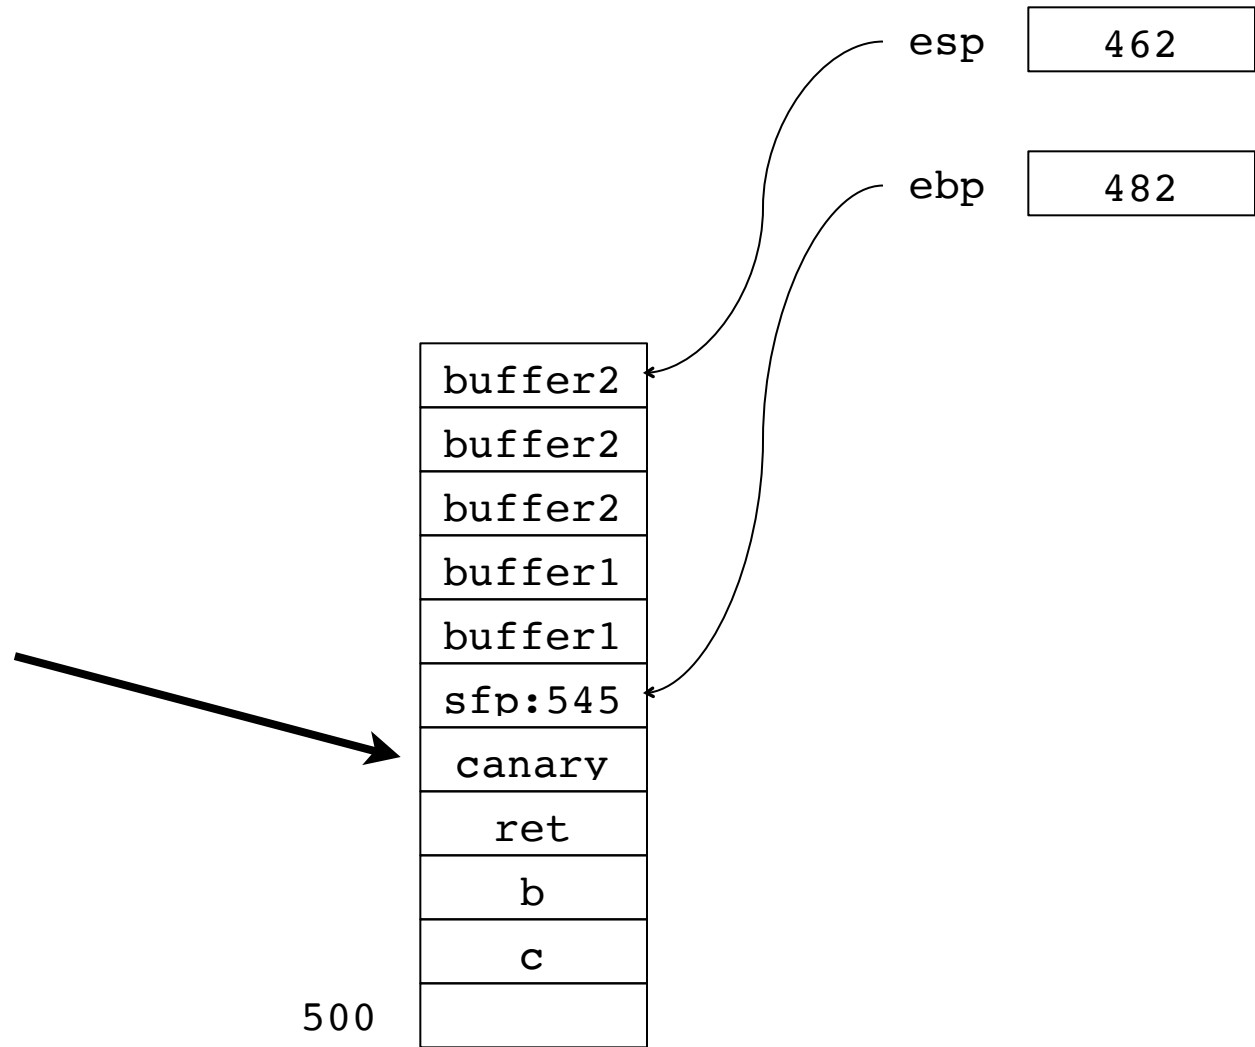

# Let's Get Creative...

We don't even have to know the exact address of the start of the buffer.

# StackGuard

```

int f (char ** argv)
{
    int pipa; // useless variable
    char *p;
    char a[30];
    p=a;
    printf ("p=%x\t -- before 1st strcpy\n",p);
    strcpy(p,argv[1]); // <== vulnerable strcpy()
    printf ("p=%x\t -- after 1st strcpy\n",p);
    strncpy(p,argv[2],16);
    printf("After second strcpy ;)\n");
}

main (int argc, char ** argv) {
    f(argv);
    execl("back_to_vul","",0); //<-- The exec that fails
    printf("End of program\n");
}

```
